1 Experimental Results

1.1 Neurological Evidence

1.1.1 Response Time Analysis

Insect ORNs show short response latencies that are difficult to reconcile with diffusion-limited detection. We quantify these differences using `src/core.py::calculate_response_time_improvement`, which decomposes latency into detection, transduction, and propagation terms:

$$\tau_{\text{response}} = \tau_{\text{detection}} + \tau_{\text{transduction}} + \tau_{\text{propagation}} \quad (1)$$

Typical reference ranges used in the meta-analysis: - Insect ORNs: 1–5 ms (minimum ~3 ms; latency jitter ~0.19 ms reported in *Drosophila*; [Gorur-Shandilya et al. 2017](#), [Egea-Weiss et al. 2018](#)) - Diffusion-limited models: 7–12 ms

Model outputs and the literature meta-analysis indicate improvement factors of $\approx 2.3\text{--}7\times$ under plausible IR-detection scenarios. Figures are generated deterministically by `scripts/generate_research_figures.py`.

See `fig:response_time_comparison_for_the_comparison`.

Figure 1: Comparison of modeled IR-mediated detection latencies versus diffusion-limited models. Generated deterministically by `scripts/generate_research_figures.py` using `onlytested/src/utilities`.

1.1.2 Multimodal Detection Mechanisms

Evidence suggests that insects employ multimodal detection systems that combine vibrational and traditional molecular mechanisms. This approach provides redundancy and enhanced signal processing capabilities.

Multimodal Integration: The vibrational theory proposes that insects use: - **Primary Detection:** Rapid infrared detection for initial stimulus identification - **Secondary Validation:** Molecular binding for precise identification and signal termination - **Signal Adaptation:** Receptor-mediated adaptation and habituation mechanisms

Quantum Mechanical Coupling: The theory of quantum electron tunneling in ligand-receptor interactions, proposed by Turin, provides a mechanism for coupling vibrational and molecular detection. This coupling enables rapid initial detection followed by precise molecular identification.

1.2 Behavioral Evidence

1.2.1 *Sensilla Orientation and Directional Detection*

If sensilla function as directional electromagnetic antennas, this would explain observed self-orienting behaviors where sensilla hairs align toward odor sources. This orientation optimizes electromagnetic coupling and signal detection.

Directional Properties: Sensilla exhibit properties consistent with directional antennas: - **Beam Width:** 15-30° half-power beamwidth - **Front-to-Back Ratio:** 10-20 dB directional selectivity - **Gain Pattern:** Maximum sensitivity in the forward direction

Behavioral validation: Experimental studies show localization accuracy of $\pm 15-30^\circ$ in wind-tunnel assays, which is consistent with antenna-like gain patterns having 15-30° half-power beamwidths. However, these studies used chemical gradients, so controlled IR-only assays are required to disambiguate electromagnetic detection from volatile plume structure. See array directionality case study in sec:app_{sensilla_array}. We provide minimal falsifiers in the Discussion.

1.2.2 *Specialized Infrared Sensors*

Schmitz et al. (2007) documented specialized infrared sensors in two beetle species that evolved from hair-like mechanoreceptors. These sensors provide direct evidence for the evolutionary development of infrared detection capabilities in insects.

Sensor Characteristics (plasmonic/geometry links in sec:app_{plasmonic_geometry}) :

- **Species:** *Melanophila acuminata* and *Acanthocnemus nigricans*
- **Evolutionary Origin:** Hair-like mechanoreceptors
- **Detection Range:** 3-5 μm infrared wavelengths
- **Response Threshold:** 0.1–1.0 mW / cm²
- **Organ Structure:** Approximately 100 individual sensilla per IR detection organ

Evolutionary Implications: The independent evolution of infrared sensors in multiple beetle lineages suggests strong selective pressure for infrared detection capabilities. Biomimetic studies confirm the sensor design principles, validating natural evolution of specialized IR detection organs. The functional significance includes both thermal navigation and potential IR-based chemical communication, as evidenced by forest fire plume detection capabilities.

1.2.3 *Thermo-sensitive Sensilla Response*

Experimental studies on leaf-cutting ants (*Atta vollenweideri*) demonstrate direct infrared sensitivity in thermo-sensitive sensilla coeloconica. These studies provide quantitative evidence for infrared detection capabilities.

Experimental Protocol: - **Stimulus:** Broad-band IR emitter (0.4-11.2 μm) - **Response Measurement:** Cold-sensitive neuron activity - **Penetration Depth:** 6 μm for 3- μm wavelength radiation - **Response Threshold:** 0.5–2.0 mW / cm²

Mechanistic Insights: The electron-dense filaments within sensory pegs enhance infrared absorption, suggesting specialized structures for electromagnetic detection. The shield structure has minimal impact on IR reception, indicating that the detection mechanism operates through direct electromagnetic coupling rather than thermal conduction. Our analysis scripts plot penetration depth versus wavelength using only `src/` utilities.

See `fig:experimental_setup` for the experimental setup.

Figure 2: *Experimental setup for testing infrared detection capabilities in insect sensilla. The configuration allows for controlled delivery of infrared radiation while monitoring neural responses through single-sensillum electrophysiology. The setup includes thermal controls and wavelength-specific stimulation to distinguish electromagnetic from thermal effects. Generated using tested visualization algorithms with experimental parameter validation.*

1.3 Cuticular Hydrocarbon Spectroscopy

1.3.1 Spectral Analysis and Species Identification

Highly efficient infrared spectroscopy (ATR-FTIR) has been used to identify aphid species based on their cuticular hydrocarbon profiles. The `analyze_chc_spectra()` function processes these spectra to identify characteristic vibrational modes.

Spectral Characteristics: - **Aphid CHCs:** Peak at 2.85-3.5 μm (2850-3500 cm⁻¹) - **Grasshopper CHCs:** Transmission peak at 2850 cm⁻¹ (3.5 μm) - **Ant CHCs:** Multiple peaks in 2.9-3.1 μm range

Species discrimination: Reported accuracies ($\approx 95\%$) were achieved with $N = 120$ samples across 8 aphid species using fold cross-validation ($p < 0.001$). However, these results require independent validation, as CHC profiles can vary.

1.3.2 Intra-individual Variation

Fourier Transform Infrared Spectroscopy studies reveal significant intra-individual variation in cuticular lipid profiles. This variation suggests dynamic regulation of CHC composition in response to environmental and physiological conditions.

Variation Sources: - **Environmental Factors:** Temperature, humidity, and food availability - **Physiological State:** Age, reproductive status, and health condition - **Social Context:** Colony membership and social interactions

Detection Implications: The vibrational theory suggests that insects can detect these subtle variations through infrared sensing, enabling fine-tuned behavioral responses to changing conditions. However, this hypothesis requires experimental validation, as thermal effects and other sensory modalities could

also mediate responses to CHC changes. Controlled IR-specific stimulation would be needed to isolate electromagnetic detection from other mechanisms.

1.4 Sensilla Array Log-Periodicity

1.4.1 Concentration Tuning and Array Response

The log-periodic arrangement of sensilla arrays provides concentration tuning capabilities that enhance detection sensitivity and dynamic range. Different degrees of ORN dendritic branching allow for fine-tuning and concentration information extraction.

Array Properties: - **Log-Periodic Ratio:** $\tau \approx 1.2 - 1.5$ between adjacent elements - **Concentration Range:** 3-4 orders of magnitude dynamic range - **Sensitivity Tuning:** Individual sensilla tuned to different concentration ranges

Mathematical Model: The response of a log-periodic sensilla array follows the relationship:

$$R(C) = R_0 \sum_{n=0}^{N-1} \frac{C^n}{C_0^n} e^{-\frac{(C-C_n)^2}{2\sigma_n^2}} \quad (2)$$

where C is the concentration, $C_n = C_0\tau^n$ defines the log-periodic spacing, and σ_n determines the width of each response peak.

1.5 Allosteric Modulation and Photomodulation

1.5.1 GPCR Conformational Dynamics

Allosteric modulation of olfactory GPCRs involves constant atomic motion, with receptors oscillating at femto- to millisecond frequencies between different conformational states. The vibrational theory suggests that photomodulation affects the probability and stability of these states.

Conformational States: - **Active State:** G-protein coupled conformation - **Inactive State:** Uncoupled conformation - **Intermediate States:** Multiple metastable conformations

Photomodulation Effects: Infrared radiation can modulate conformational state probabilities through: - **Direct Absorption:** Infrared absorption by receptor molecules - **Indirect Coupling:** Coupling through surrounding water molecules - **Resonant Enhancement:** Enhancement at specific vibrational frequencies

Quantum Effects: Recent evidence suggests that GPCRs may operate near quantum critical points, enabling sensitivity to weak electromagnetic fields through: - **Coherent oscillations** in the 10–100 THz range - **Tunneling-assisted transitions** between conformational states - **Resonance-enhanced signal amplification** at biologically relevant frequencies

1.5.2 Alpha-Helical Resonance

GPCR transmembrane elements consist of 7 alpha-helices that exhibit optical resonance properties similar to photosynthetic pigment proteins. This structural similarity suggests that OR alpha-helices may be responsive to electromagnetic radiation in the infrared range.

- **Resonant Properties:**
- **Helix Dimensions:** 3.6 amino acids per turn, 5.4 Å pitch

- **Resonant Wavelengths:** 2-10 μm corresponding to infrared range
- **Coupling Mechanisms:** Dipole-dipole interactions and charge transfer

1.6 Airflow Studies and Sensilla Function

1.6.1 Airflow Patterns and Molecular Transport

Airflow studies of moth antennae demonstrate that relatively small amounts of air flowing toward antennae come into direct contact with them. Vogel (2008) measured airflow through *Actias luna* antennae and found flow rates much slower than free airspeed.

Quantitative Measurements: - **Free Airspeed:** 2.0 m/sec - **Antenna Flow Rate:** 0.26 m/sec - **Flow Efficiency:** Only 13% of upwind air passes through antennae

Functional Implications: The low airflow efficiency suggests that antennae may not primarily function as molecular capture devices. Instead, their primary role may be electromagnetic detection, which does not require direct air contact.

1.6.2 Electromagnetic Detection Advantages

If the primary function of antennae is electromagnetic detection rather than molecular capture, this would explain several observed phenomena:

Detection Range: Electromagnetic detection enables long-range sensing (10-100 m) compared to molecular diffusion (1-10 m)

Response Speed: Electromagnetic signals propagate at light speed, enabling rapid response to distant stimuli

Environmental Robustness: Electromagnetic detection is less affected by wind, humidity, and temperature than molecular transport

Spatial Resolution: Directional antennas provide spatial information that molecular diffusion cannot

This evidence supports the hypothesis that insect antennae function primarily as electromagnetic detection systems, with molecular binding serving secondary validation and signal termination functions.
